Abstract

A new species of Polygonatum, P. annamense based on evidence from herbarium studies, molecular data, and cultivated material is described and illustrated from upper elevations of the southern Annamite ecoregion where it occurs disjunctly in both the Central Highlands and the Đà Lạt Plateau, Vietnam. It is compared to the morphologically similar P. punctatum with which it has been confused, and its relationship to P. mengtense, P. punctatum, and P. urceolatum is discussed.

Key words: Annamites, endemic, Sino-Himalaya

Introduction

Recent collections of a Polygonatum Miller (1754: without pagination) (Asparagaceae, Reveal & Chase 2011) by the International Botanical Expedition of the US National Geographic Society (see below) and a living collection (BSWJ9752) from the Central Highlands of Vietnam support the recognition of an undescribed species based on morphological comparisons to P. mengtense Wang & Tang (1936: 84) from northern Vietnam (see also Floden 2014), P. punctatum Royle ex Kunth (1850: 142) from the Himalaya, and P. urceolatum (Shaw 2009: 174) Floden (2014: 112) from northeast Vietnam and adjacent China.

What few collections that exist of Polygonatum annamense have remained in a broad morphologically and phytogeographically discontinuous circumscription of P. punctatum. This species occurs only in upper elevation cloud forests in a small region of the Annamite ecoregion that includes the Central Highlands and the Đà Lạt Plateau which restricts its available habitat due to the limited area that reaches elevations above 1400 meters. Due to this reduced area of suitable habitat, its presumed rarity, and the limited floristic inventory in Vietnam (and neighboring Laos) it is unsurprising that this novel species has only recently been revealed. Newman et al. (2007) reported that there are approximately 14 collections per 100 km² for Vietnam (adjacent Laos is reported at three per 100 km²). In fact, P. annamense has been reported as P. punctatum from Kon Tum Province (Le Trong et al. 1999) though the actual distribution of P. punctatum is confined to the Himalayan Mountains (Sino-Himalayan floristic region) (Floden 2014).

Polygonatum is a genus of 60 or more species that are circumboreal in distribution with its center of diversity concentrated in southwest China, the Sino-Himalayan region, and a secondary center of diversity in northeast China, the Koreas and Japan (Tamura 1990). Infrageneric classification of the genus is currently based on phyllotaxy (alternate, opposite, or verticillate), filament shape, and cytology (Tamura 1990, 1991, 1993). Filament shape is mostly correlated to the base chromosome number, although limited molecular work has not supported these morphologically defined groups as monophyletic (Tamura et al. 1997; Wu et al. 2000). Nonetheless, delimitation between closely related species is best facilitated by the distribution and type of epidermal features of the filaments (Tamura 1990, 1991, 1993).

Two species endemic to the Sino-Himalayan region are unique in being opposite or alternate leaved, evergreen, having a base chromosome number of x = 15, red fruit, and an epiphytic habitat. Polygonatum oppositifolium (Wallich 1820: 380) Royle (1839: 380) has opposite leaves and not discussed further, whereas P. punctatum has leaves that are spirally alternate, opposite, or terminally verticillate. Based on observations of specimens and field observations, and confirmed by molecular data (A. Floden, in preparation), it is part of a clade containing P. punctatum and several Indochinese species isolated at high elevations distributed disjunctly in Thailand, northern and southern Vietnam, and southwest China. Latitudinal distribution of the genus ranges from the north of Russia where several taxa occur south into Indochina where P. annamense is the southernmost distributed species in the genus.

The description of this new species endemic to the Central Highlands of Vietnam increases the number of species to four in this group of *Polygonatum*. All the species of this group are distributed from the Himalaya south and east into floristically Sino-Himalayan zones as defined by elevation in otherwise Sino-Japanese or Malayan floristic regions (Averyanov et al. 2003). *Polygonatum annamense* represents an additional Sino-Himalayan floristic element of the Ngoc Linh Mountain area and the Đà Lạt Plateau. Both are areas of elevated floral endemism and also an intersection of the Sino-Himalayan and Malayan floristic provinces, the former found mostly at upper elevations (Sterling & Hurley 2005, Le et al. 1999).

Acknowledgements

I thank Leonid Averyanov for remarks about his collections of this species, Bleddyn and Sue-Wynn Jones for introducing this species into cultivation, Dr. Solomon and the staff at MO for assistance while at the herbarium, the staff at P for digitization of specimens, and Dr. T. Mitchell for providing a living plant of this species for study.
